1 Monoids

1. (a) There is a monoid called the *free monoid*. It has this name because it allows you to give any type a monoid instance for free. Can you think what it is?

   > **Solution:** The list monoid ($\langle [a], +\!\!+, [] \rangle$) because any data type can be wrapped into a list and thus have this monoid. Freebie.

   (b) Prove that the *free monoid* is a monoid.

   > **Solution:**
   >
   > To be a monoid $\langle [a], +\!\!+, [] \rangle$ must uphold the monoid laws:
   >
   > | | | |
   > |---|---|---|
   > | 1. | Left identiy | $\varnothing \oplus x = x$ |
   > | 2. | Right identity | $x \oplus \varnothing = x$ |
   > | 3. | Associativity | $(x \oplus y) \oplus z = x \oplus (y \oplus z)$ |
   >
   > Proof:
   >
   > Using the definition of $(+\!\!+)$:
   >
   > $(+\!\!+) :: [a] \to [a] \to [a]$
   > $[] +\!\!+ ys \quad = ys$
   > $(x : xs) +\!\!+ ys = x : (xs +\!\!+ ys)$
   >
   > Left identity:
   >
   > $\quad [] +\!\!+ ys$
   > $=== \quad \{-(+\!+) -\}$
   > $\quad ys$
   >
   > Right identity:
   > Case: $[]$
   >
   > $\quad [] +\!\!+ []$
   > $=== \quad \{-\text{definition of } +\!\!+ -\}$
   > $\quad []$
   >
   > Case: $(x : xs)$
   >
   > $\quad (x : xs) +\!\!+ []$
   > $=== \quad \{-\text{definition of } +\!\!+ -\}$
   > $\quad x : (xs +\!\!+ [])$
   > $=== \quad \{-\text{induction hypothesis} -\}$
   > $\quad (x : xs)$
   >
   > And for the associativity proof see week 2 answers, reverse proof, lemma 2.

2. A semi-group is a type equipped with an associative binary operation i.e. a Monoid without an identity element.

   Write a type class to represent a Semigroup.

   > **Solution:**

```
class Semi s where
    binop :: s → s → s
```

3. (Code) Define two Semigroup and Monoid instances for Booleans that can live in the same Haskell file together without Haskell getting upset.

> **Solution:**
>
> ```
> newtype BooleOR = BooleOR Bool
>
>
> instance Semigroup BooleOR where
>     (<>) (BooleOR x) (BooleOR y) = BooleOR (x || y)
>
>
> instance Monoid BooleOR where
>     mempty = BooleOR False
>     mappend (BooleOR x) (BooleOR y) = BooleOR (x || y)
>
>
> newtype BooleAND = BooleAND Bool
>
>
> instance Semigroup BooleAND where
>     (<>) (BooleAND x) (BooleAND y) = BooleAND (x || y)
>
>
> instance Monoid BooleAND where
>     mempty = BooleAND True
>     mappend (BooleAND x) (BooleAND y) = BooleAND (x && y)
> ```

4. † (a) What is the difference between $(xs \mathbin{+\!\!+} ys) \mathbin{+\!\!+} zs$ and $xs \mathbin{+\!\!+} (ys \mathbin{+\!\!+} zs)$?

> **Solution:** Since this is a monoid the result of these two expressions is the same. However, $(xs \mathbin{+\!\!+} ys) \mathbin{+\!\!+} zs$ is very inefficient. This expression is an $O(n^2)$ operation.
>
> The intuition of why it is inefficient is that the left most list (xs) gets unpacked for each $\mathbin{+\!\!+}$. For example, in the expression $(((xs \mathbin{+\!\!+} ys) \mathbin{+\!\!+} zs) \mathbin{+\!\!+} ps)$ you can imagine each element of xs being prefixed to ps, then each element of $(xs \mathbin{+\!\!+} ys)$ being prefixed to zs, and then each element of $((xs\mathbin{+\!\!+}ys)\mathbin{+\!\!+}zs)$ being prefixed to ps. This leads to xs being unpacked multiple times, a redundant operation.
>
> However, because Haskell is lazy the reason it is inefficient is not as straightforward as that. The latent inefficiency is caused by the way that Haskell manages its memory. Instead of Haskell unpacking xs many times it actually stores the fact that it needs to do this as a big unevaluated *thunk* structure. When prompted for an answer, Haskell is forced to wade through the *thunk* structure to get the result, slowing it down to an $O(n^2)$ operation.

   (b) Which way does Haskell bracket $xs \mathbin{+\!\!+} ys \mathbin{+\!\!+} zs$ by default?

> **Solution:** $xs \mathbin{+\!\!+} (ys \mathbin{+\!\!+} zs)$. $(\mathbin{+\!\!+})$ is deliberately defined to be right associative in the Prelude, binding to the right element since it is more efficient.

5. † (a) (Code) Define the monoid instance for:

```
newtype Function a = Function (a → a)
```

† (b) Prove that this obeys the monoid laws.

6. Is it possible to create an instance of a monoid that does not uphold the monoid laws? If so, why, and give an example by defining the instance and saying which laws it breaks. If not, explain how invalid instances are restricted.

```
    instance Monoid Integer where
        mempty   = 1
        mappend = (^)
```

As a bonus exercise, you should check to see which laws are violated.

---

† 7. A group $(G, *)$ is a set G together with a binary operation $* : G \to G \to G$ satisfying the following properties:

1. (Associativity) $\forall\, x, y, z \in G, \ (x * y) * z = x * (y * z)$
2. (Identity) $\exists\, e \in G$, such that $\forall\, x \in G: x * e = x = e * x$
3. (Inverse) $\forall\, x \in G, \exists\, x^{-1} \in G$, such that: $x * x^{-1} = e = x^{-1} * x$

(a) (Code) Define a type class for groups.

Solution:

```
    class Group a where
        op       :: a → a → a
        identity :: a
        inverse  :: a → a
```

or if you think about the fact that *group*s are monoids with an inverse:

```
    class Monoid a ⇒ Group′ a where
        inverse′ :: a → a
```

(b) (Code) Define a sensible instance of your type class that upholds properties of a group.

Solution:
Addition over the Integers:

```
    instance Group Integer where
        op a b   = a + b
        identity = 𝟘
        inverse a = − a
```
